Abstract. In this paper we investigate the existence of a deductive verification method based on a logic that describes pointer aliasing. The main idea of such a method is that the user has to annotate the program with loop invariants, pre- and post-conditions. The annotations are then automatically checked for validity by propagating weakest preconditions and verifying a number of induced implications. Such a method requires an underlying logic which is decidable and has a sound and complete weakest precondition calculus. We start by presenting a powerful logic (wAL) which can describe the shapes of most recursively defined data structures (lists, trees, etc.) has a complete weakest precondition calculus but is undecidable. Next, we identify a decidable subset (pAL) for which we show closure under the weakest precondition operators. In the latter logic one loses the ability of describing unbounded heap structures, yet bounded structures can be characterized up to isomorphism. For this logic two sound and complete proof systems are given, one based on natural deduction, and another based on the effective method of analytic tableaux. The two logics presented in this paper can be seen as extreme values in a framework which attempts to reconcile the naturally opposite goals of expressiveness and decidability.

1 Introduction

The problem of pointer aliasing plays an important role in the fields of static analysis and software model checking. In general, static analyses used in optimizing compilers check basic properties such as data sharing and circularities in the heap of a program, while model checking deals with the evolution of heap structures, in both shape and contents, over time. An early result [21] shows that precise may-alias analysis in the presence of loops is undecidable. As a consequence, the approach adopted by the static analysis community, is the abstraction-based shape analysis [23]. This method is effective in the presence of loops, since the domain of the analysis is bounded, but often imprecise. In this paper we present an orthogonal solution to the aliasing problem, in that precision is the primary goal. To ensure termination, we use Floyd’s method [10] of annotating the program with pre-, post-conditions and loop invariants. The annotations are subsequently verified by a push-button procedure, that computes weakest preconditions expressed using an effectively decidable logic.
The key is to find a logic that can altogether (i) express aliasing and shape properties of the program heap, (ii) is effectively decidable, and moreover, (iii) has a sound and complete weakest precondition calculus with respect to the atomic statements. While the second and third requirements are clear, the first one is still ambiguous: what kind of specifications can we express in a decidable heap logic with weakest preconditions? The contribution of this paper is the definition of a formal framework in which we prove that such logics can be found. Our focus is on imperative programs with destructive updating, in which heaps are viewed as shape graphs with labels only on edges i.e., we ignore from the start the internal states of the objects.

As a starting point, we present a general logic Weak Alias Logic (wAL) that is expressive enough to describe the recursive data structures of interest (lists, trees, stacks etc.) as infinite classes of finite graphs. This logic has also a sound and complete weakest precondition calculus with respect to atomic statements such as new object creation and assignment of pointers. The satisfiability problem of the wAL logic is found to be undecidable but recursively enumerable, which motivates further searches for semi-decision procedures and non-trivial decidable subsets.

In the rest of the paper, we define a decidable subset of wAL, called Propositional Alias Logic (pAL) for describing pointer aliasing that is, moreover, able to characterize arbitrary finite structures and finite classes of structures. The tradeoff in defining pAL is losing the ability to describe a number of interesting shape properties such as listness, (non)circularity, etc. For this logic, we give a proof-theoretic system based on natural deduction, and an effective tableau decision method. Both systems are shown to be sound and complete. Moreover, the satisfiability problem for pAL is shown to be NP-complete. The last point concerns the definition, in pAL, of weakest preconditions for imperative programs with destructive updating. At this point, we use the wAL weakest precondition calculus, previously developed in [2]. Our weakest precondition calculus for pAL is sound and complete, as a consequence of the soundness and completeness of the definitions for wAL weakest preconditions.

Related Work To describe properties of dynamic program stores, various formalisms have been proposed in the literature e.g., $L_r$ [1], BI (Bunched Implications) [13], Separation Logic [22] and PAL (Pointer Assertion Language) [17]. As a common point with our work, $L_r$ [1] uses regular expressions to describe reachability between two points in the heap and is shown to be decidable, yet the weakest precondition calculus is not developed. On the other hand, BI [13] and Separation Logic [22] produce remarkably simple preconditions and have quite clean proof-theoretic models [18]. Another feature of these formalisms is that they allow for compositional reasoning [19]. As a downside, the quantifier fragment, essential to express weakest preconditions, is undecidable [5], while the ground (propositional) fragment is decidable, a tableau procedure being proposed in [11]. In a later publication [6], a specialization of the ground fragment of BI to tree models is used as a type system for a language, based on $\lambda$-calculus, that handles trees. An effectively decidable formalism is PAL [17], an extension
of second-order monadic logic on trees that allows to describe a restricted class of graphs, known as “graph types” [16], as opposed to our approach that deals with unrestricted graphs. Programs that manipulate such graphs are restricted to updating only the underlying tree (backbone). The resulting actions can thus be described in monadic second-order logic, and the validity of Hoare triples expressed in PAL can be automatically decided [15].

The decision procedures for both $L_r$ and PAL use Rabin’s result on the monadic second order theory of $n$ successors (SuS) [20]. The decision procedure for the satisfiability of SuS is however non-elementary. We show that the decision problem for the pAL logic is NP-complete, thus drastically improving the complexity bounds. Also, to the best of our knowledge, no previously published work on the verification of heap properties has the ability to deal with unrestricted (destructively updated) data structures, developing a sound and complete weakest precondition calculus on top of a decidable logic for graphs.

2 Weak Alias Logic

In this section we introduce Weak Alias Logic (wAL), a logic that is expressive enough for defining recursive data structures (lists, trees, etc) as infinite classes of finite graphs, as well as for defining a weakest precondition calculus of imperative programming languages with destructive updating [2]. This section defines the logic, and Section 5 briefly recalls the weakest precondition calculus that has been developed on top of it.

Before giving the syntax of wAL, let us introduce the notion of heap, which is central in defining interpretations of wAL formulas. Intuitively, a heap is represented by a graph where the nodes model objects and the edges model pointers between objects. The heap edges are labeled with symbols from a given alphabet $\Sigma$, which stands for the set of all program pointers, including all program variables and record fields (selectors). It is furthermore required that the graph be deterministic, as a program pointer can only point to one object at a time.

In this paper we adopt the storeless representation [2], [12], [14], [8] of a graph, in which each node is associated the language recognized by the automaton whose set of states is given by the set of graph nodes, the transition relation by the set of edges, the initial state is a designated entry point in the heap, and the unique final state, the node itself. The interested reader is referred to [2] for a detailed discussion on the advantages of the storeless representation of heaps, such as compatibility with garbage collection and isomorphic transformations.

**Definition 1 (Heap).** A heap $M \subseteq \mathcal{P}(\Sigma^+)$ is either the empty set or a finite set $\{X_1, X_2, \ldots, X_n\}$ satisfying the following conditions, for all $1 \leq i, j \leq n$:

- (C1) non-emptiness: $X_i \neq \emptyset$,
- (C2) determinism: $i \neq j \Rightarrow X_i \cap X_j = \emptyset$,
- (C3) prefix closure and right regularity:

\[
\forall x \in X_i \left[ \forall y, z \in \Sigma^+ [x = yz \Rightarrow \exists 1 \leq k \leq n \ [y \in X_k \land X_k z \subseteq X_i]] \right]
\]
One can also think of a heap element as the set of all incoming paths leading to it, paths that start with a program variable. The (C1), (C2) and (C3) restrictions must be imposed on the elements of a heap in order to maintain the correspondence (up to isomorphism) with the graph model [2]. An equivalent approach, taken in [14, 8], is to consider the languages in the heap as equivalence classes of a right-regular relation on $\Sigma^* \times \Sigma^*$. The set of all heaps over an alphabet $\Sigma$ is denoted in the following by $\mathcal{H}(\Sigma)$.

Figure 1 introduces the abstract syntax (upper part) and semantics (lower part) of the $\text{wAL}$ logic. The terms of a $\text{wAL}$ formula are regular expressions $\rho$ over the alphabet $\Sigma$ with free variables from a set $\text{Var}$. We allow the classical composition operations on regular expressions, together with the left derivates, denoted by $\rho_1 \blacktriangleleft \rho_2 \overset{1}{\triangleleft} \{ \sigma \in \Sigma^* \mid \rho_1 \sigma \blacktriangleleft \rho_2 \neq \emptyset \}$. Formulas are built from the atomic propositions $\rho_1 = \rho_2$ (language equivalence) and $\langle X \rangle \rho_1$ (modality) connected with the classical first-order operators $\land, \lor$ and $\exists$. A less usual requirement is imposed on the syntax of the existential quantifier: the quantified variable need to occur at least once within the angled brackets of a modality in the scope of the quantifier, which is formally captured by the $\varphi(X)$. Notice also that only free variables can occur inside the modality brackets. A formula $\varphi$ is said to be closed if no variables occur free i.e., $FV(\varphi) = \emptyset$, where $FV$ is defined recursively on the syntax, as usual. We define $\forall X . \varphi \overset{\Delta}{=} \neg \exists X . \neg \varphi$, $\varphi_1 \lor \varphi_2 \overset{\Delta}{=} \neg \neg \varphi_1 \land \neg \varphi_2$, and $\varphi_1 \rightarrow \varphi_2 \overset{\Delta}{=} \neg \varphi_1 \lor \varphi_2$. The set of all $\text{wAL}$ formulas over the alphabet $\Sigma$ is formally denoted by $\text{wAL}[\Sigma]$.

$$\begin{align*}
\rho &::= v \in \Sigma \mid X \in \text{Var} \mid \Sigma \mid \rho_1 \cdot \rho_2 \mid \rho^* \mid \rho_1 \lor \rho_2 \mid \rho_1 \land \rho_2 \mid \rho \mid \rho_1 \ominus \rho_2 \\
\varphi &::= \rho_1 = \rho_2 \mid \langle X \rangle \rho_1 \mid \varphi_1 \land \varphi_2 \mid \neg \varphi \mid \exists X . \varphi(X)
\end{align*}$$

**Fig. 1.** Weak Alias Logic

A $\text{wAL}$ formula is interpreted with respect to a heap $M$ and a valuation $\nu$ assigning free variables to languages. The only non-standard operator is the modality $\langle X \rangle \rho_1$, where $X$ is bound to denote a heap entity which intersects (the interpretation of) $\rho_1$. As a consequence of the syntactic restriction imposed on the existential quantifier, all variables in a closed formula are bound to heap

---

1 Intuitively, we need the left derivates to describe paths between two objects in the heap. If $X$ and $Y$ are two objects in a heap, then $X^{-1}Y$ is the language of all paths between $X$ and $Y$.  

---

3
A heap $M$ is said to be a model for a closed wAL formula $\varphi$ if and only if $[\varphi]_{M,\lambda,\lambda_{\perp}} = 1$. In case where $\varphi$ has at least one model, it is said to be satisfiable.

At this point, the reader can notice an embedding of wAL into the Monadic Second Order Logic on graphs. Indeed, a wAL formula is composed of equivalences of regular expressions ($\rho_1 = \rho_2$) related using first order connectives. Such equivalences can be described by finite automata which, in turn, can be specified in MSOL. However, we found using regular expressions, instead of MSOL, more intuitive for the specification of heap properties, as it is shown in the following.

Fig. 2. Expressing properties of heaps

The properties in Figure 2 describe various paths in the structure. We consider the predicate $\text{reach}(X,Y)$ stating that node $Y$ is reachable from node $X$ by some non-empty path. A node $Y$ is said to be next to a node $X$ if $Y$ is the only neighbor of $X$. A path from $X$ to $Y$ is linear if there is no branching i.e., if all the nodes on the path have only one successor. The existence of a cycle containing both $X$ and $Y$ is given by the $\text{cycle}(X,Y)$ predicate.

The wAL logic can also describe the shapes of most typical recursive data structures used in programming languages with dynamic memory allocation: lists, trees, stacks, etc. For instance, non-cyclic simply-linked lists pointed to by the $\text{head}$ variable and using the $\text{next}$ field as forward selector, are being described by the $\text{nclist}$ predicate. Doubly-linked lists pointed to by the $\text{head}$ variable and using the $\text{next}$ and $\text{prev}$ field pointers as forward and backward selectors, respectively, can be captured by the $\text{dllist}$ predicate. Some data structures, such as trees, require the absence of sharing. A sharing predicate expressing that $X$ and $Y$ belong to two structures that share some node can be given by $\text{share}(X,Y)$. A tree structure pointed to by a variable $\text{root}$ is described by the $\text{tree}$ formula.

---

2 This syntactic restriction on the quantification domain was mainly suggested by the fact that, allowing quantification over $P(\Sigma^*)$ makes the logic undecidable even when modalities are not used at all in formulas. A formal proof will be included in an extended version of this paper.
dag structure in which every node is reachable from a root variable is given by the *dag* formula.

2.1 Undecidability of wAL

The result of this section comes with no surprise, in the light of similar undecidability results for logics able to express graph properties such as, e.g., the logic of Bunched Implications (BI) [5], and Monadic Second-Order Logic of graphs [7]. Given along the same lines as the undecidability proof for BI [5], our proof for wAL relies on a classical result in finite model theory [9], namely that the first order logic interpreted over finite structures is undecidable.

Given a vocabulary $\mathcal{V}$ of relation symbols, let $\text{FO}[\mathcal{V}]$ be the set of first-order formulas with symbols from $\mathcal{V}$. For each relation symbol $R \in \mathcal{V}$, let $\#(R)$ denote its *arity* i.e., its number of arguments. Let $\mathcal{V} = \{R_1, \ldots, R_n\}$ for the rest of this section. We interpret first-order formulas over structures $\mathcal{A} = \langle A, R_1^A, \ldots, R_n^A \rangle$, where $A$ is the *universe* and $R_i^A \subseteq A^{\#(R_i)}$, $1 \leq i \leq n$ are the interpretations of the relation symbols from $\mathcal{V}$ over $A$. A structure is said to be *finite* if and only if its universe is finite. Given a valuation $v : \text{FV}(\varphi) \rightarrow A$ of the free variables in a formula $\varphi \in \text{FO}[\mathcal{V}]$, we denote by $[\varphi]_{\mathcal{A},v}$ the interpretation of $\varphi$ in $\mathcal{A}$. We say that $\mathcal{A}$ is a *model* of a closed first-order formula $\varphi$ if and only if $[\varphi]_{\mathcal{A},v} = 1$.

It is known that the problem of finding a finite model for a closed $\text{FO}[\mathcal{V}]$ formula is undecidable [9].

**Theorem 1 (Trakhtenbrot’s Theorem).** Let $\mathcal{V}$ be a vocabulary with at least one symbol of arity two or more. Then the set $\text{Sat}[\mathcal{V}] \triangleq \{ \varphi \in \text{FO}[\mathcal{V}] \mid \text{FV}(\varphi) = \emptyset, \varphi \text{ has a finite model} \}$ is not decidable.

Given an arbitrary first order formula, we shall translate it into a $\text{wAL}$ formula such that satisfiability is strongly preserved by the translation. Considering that $\mathcal{V} = \{R_1, \ldots, R_n\}$, we define

$$\Sigma_{\mathcal{V}} = \{ \alpha_{i1}, \ldots, \alpha_{i\#(R_i)} \mid 1 \leq i \leq n \} \cup \{ \gamma \}.$$  

That is, for each relation symbol of arity $k$ we consider $k$ different $\alpha$-symbols and a $\beta$-symbol in $\Sigma_{\mathcal{V}}$. The translation is given by the recursive function $\Theta : \text{FO}[\mathcal{V}] \rightarrow \text{wAL}[\Sigma_{\mathcal{V}}]$, defined as:

$$\Theta(R_i(X_1, \ldots, X_{\#(R_i)}) \triangleq \exists X : \langle X \rangle \Sigma^* \land \bigwedge_{i=1}^{\#(R_i)} \langle X \rangle \alpha_{is}$$

$$\Theta(X = Y) \triangleq X = Y$$

$$\Theta(\varphi_1 \land \varphi_2) \triangleq \Theta(\varphi_1) \land \Theta(\varphi_2)$$

$$\Theta(\neg \varphi) \triangleq \neg \Theta(\varphi)$$

$$\Theta(\exists X : \varphi) \triangleq \exists X : \langle X \rangle \Sigma^* \land \Theta(\varphi)$$

Note that the translation of a closed first-order formula respects the syntactic constraints of $\text{wAL}$, that each quantified variable must occur inside the brackets of a modality, and that only a variable can occur on this position. Moreover, a closed first-order formula translates into a closed $\text{wAL}$ formula. Now it remains to be shown that the translation strongly preserves satisfiability. We remind that satisfiability for $\text{wAL}$ is implicitly defined on finite models (Definition 1). Due to space constraints, all proofs are deferred to [3].

**Lemma 1.** A closed first-order formula $\varphi$ is finitely satisfiable if and only if $\Theta(\varphi)$ is satisfiable.
Considering for the moment that the alphabet $\Sigma$ is sufficiently large to code the vocabulary $\mathcal{V}$ of a given first order logic, Theorem 1 and Lemma 1 lead immediately to the following result.

**Theorem 2.** For a sufficiently large alphabet $\Sigma$, the set $\text{Sat}(\Sigma) \triangleq \{ \varphi \in \text{wAL}(\Sigma) \mid FV(\varphi) = \emptyset, \ \varphi \text{ has a model} \}$ is not recursive.

Since Theorem 1 holds for vocabularies containing at least one relation symbol of arity two, by the definition of $\Sigma_\mathcal{V}$ it follows that Theorem 2 holds for generic heaps over alphabets of size at least four. Here, a more refined heap model could provide us with more intuition in identifying classes of heaps over which the satisfiability problem becomes decidable. For instance, considering $\Sigma = \Pi \cup \Omega$, $\Pi \cap \Omega = \emptyset$, $|\Pi| = 1$ and all heaps of the form $\mathcal{M} \subseteq \mathcal{P}(\Pi \times \Omega)$ i.e., 

heaps consisting only of (possibly circular) singly linked lists. In this simple case, we propose to revisit the decidability of the satisfiability problem for wAL.

In order to show that the satisfiability problem for wAL is recursively enumerable, let us first consider the model checking problem. The model checking problem asks whether a given heap $\mathcal{M}$ is a model for a formula $\psi$. This problem is decidable, by the fact that any heap model is finite. The interested reader is referred to [4] for an algorithm. But the set $\mathcal{H}(\Sigma)$ of all heaps over a finite alphabet is enumerable. Hence, if a given formula $\psi$ is satisfiable, an algorithm that enumerates all models $\mathcal{M}_1, \mathcal{M}_2, \ldots$, testing whether each $\mathcal{M}_i$ is a model of $\psi$, will eventually stop.

**Lemma 2.** For every finite $\Sigma$, the set $\text{Sat}(\Sigma)$ is recursively enumerable.

An interesting open problem is then how to find useful semi-decision procedures for wAL.

### 3 Propositional Alias Logic

The negative result from the previous section motivates the search for decidable subsets of wAL that are able to express meaningful properties of heaps. One basic property encountered in many applications is data sharing. In this section we define a simpler logic based directly on the notion of aliasing of finite heap access paths (Propositional Alias Logic, or pAL for short). The rest of this paper is concerned with the study of pAL from three perspectives: proof theory, automated reasoning and program logic. The ability of pAL to express other heap properties besides aliasing, is also investigated.

Figure 3 defines the abstract syntax (upper part) and the semantics (lower part) of pAL. The terms are finite words over an alphabet $\Sigma$, with $w_1^{-1} w_2$ being the suffix of $w_2$ that, concatenated with $w_1$, yields $w_2$, if such suffix exists, or the empty word $\varepsilon$, otherwise. The atomic propositions are the *prefix test* ($w_1 \triangleleft w_2$) and the *alias proposition* ($w_1 \triangleright w_2$). Formulas are built from atomic propositions connected with the propositional operators $\land$ and $\neg$. In the syntax definition, $\bot$
\[ w \equiv v \in \Sigma \mid w_1 \cdot w_2 \mid w_1 \cdot w_2 \]
\[ \varphi \equiv w_1 \leq w_2 \mid w_1 \cdot w_2 \mid \varphi_1 \land \varphi_2 \mid \neg \varphi \mid \bot \]
\[ \left[ w_1 \cdot w_2 \right]_M = 1 \iff \exists X \in M \cdot w_1, w_2 \in X \]

**Fig. 3.** Propositional Alias Logic

denotes the *false* literal\(^3\). The set of all pAL formulas over the alphabet \( \Sigma \) is formally denoted by \( \text{pAL}[\Sigma] \).

The semantics of pAL is defined with respect to a heap \( M \). An alias proposition \( w_1 \cdot w_2 \) is true if and only if there exists an element of \( M \) such that both terms \( w_1, w_2 \) belong to it. Note that, since \( M \subseteq \mathcal{P}(\Sigma^+) \), if either one of the terms is \( \epsilon \), the alias proposition is false. The intended meaning of \( w \cdot w \) for some \( w \in \Sigma^+ \), is to say that \( w \) is a well-defined path in the heap. The following semantic equivalence is a trivial check: \( w_1 \cdot w_2 \iff \exists X \cdot (X)w_1 \land (X)w_2 \). The prefix relation \( w_1 \leq w_2 \) can be encoded in wAL as \( w^{-1}_1 w_2 \neq \emptyset^* \), where \( \epsilon \neq \emptyset^* \) is a possible definition of the empty word in wAL. These considerations justify the fact that pAL is a subset of wAL. The embedding is proper \( (\text{pAL}[\Sigma] \subset \text{wAL}[\Sigma]) \), since e.g. reachability and linearity are not expressible in pAL.

### 3.1 Natural Deduction System

This section introduces a natural deduction system \([25]\) for pAL that proves to be a useful tool in reasoning about aliases. Although later in this paper we adopt the automated reasoning view, as opposed to the proof theoretic, a number of results from this sections are used in the rest of the paper. The system (Figure 4) is that of propositional calculus à la Gentzen (rules \( \land E, \land I, \neg E, \neg I, \land E, \land I \)) to which we add three rules concerning only alias propositions (suffE, suff and sym). For these rules we take \( \Gamma \subseteq \text{pAL}[\Sigma] \), \( x, y, z \in \Sigma^+ \) and \( t \in \Sigma^* \).

\[
\begin{array}{l}
\frac{x \cdot y}{x \cdot z} \quad (\text{suffE}) \\
\frac{x \cdot y}{y \cdot z} \quad (\text{suff}) \\
\frac{\varphi \land \psi}{\varphi} \quad (\land E) \\
\frac{\varphi \land \psi}{\varphi} \quad (\land I) \\
\frac{\Gamma, \varphi \vdash \bot}{\Gamma \vdash \varphi} \quad (\neg E) \\
\frac{\Gamma, \neg \varphi \vdash \bot}{\Gamma \vdash \neg \varphi} \quad (\neg I) \\
\end{array}
\]

**Fig. 4.** Natural Deduction System for pAL

\(^3\) False could have been defined as \( \varphi \land \neg \varphi \) for an arbitrary formula \( \varphi \). However an explicit definition is preferred for the purposes of the proof theoretic system of Section 3.1.
The natural deduction system presented in Figure 4 exhibits a number of interesting properties: it is sound, complete and, all proofs of alias propositions can be given in a normal form. To formalize these notions, we need further notation. If \( p \) is an alias proposition, we say that \( \Gamma \vdash_{PA} p \) if and only if there exists a derivation of \( p \) with premises in \( \Gamma \) that uses only the (suf), (sufE) and (sym) rules. Otherwise, if \( \psi \) is any formula, we say that \( \Gamma \vdash \psi \) if and only if there exists a derivation of \( \psi \) with premises in \( \Gamma \). By \( Th(\Gamma) \) we denote the theory of \( \Gamma \) i.e., the set of all formulas that can be deduced from it i.e., \( Th(\Gamma) \triangleq \{ \varphi \mid \Gamma \vdash \varphi \} \).

Given a finite set of alias propositions, there exists a heap that is a model for the entire set.

**Lemma 3.** Let \( \Gamma \) be a set of formulas containing a finite number of alias propositions, \( \approx_{\Gamma} \subseteq \Sigma^{\ast} \times \Sigma^{\ast} \) be a relation on finite sequences, defined as \( x \approx_{\Gamma} y \) if and only if \( \Gamma \vdash_{PA} x \bowtie y \), and \( H_{\Gamma} \) be the set \( \{ x \mid x \approx_{\Gamma} x \} \). Then \( \approx_{\Gamma} \) is a total equivalence relation on \( H_{\Gamma} \), and the quotient \( H_{\Gamma}/\approx_{\Gamma} \) is a heap. Moreover, \( |H_{\Gamma}/\approx_{\Gamma}| \leq k \cdot |\Gamma| \), where \( k \in \mathbb{N} \) is a constant.

Note that, for arbitrary sets of formulas, the existence of a model occurs as a consequence of the downward closure property\(^4\).

### 3.2 Expressiveness of pAL

In this section we investigate the expressiveness of the \texttt{pAL} language. We show that any finite heap structure over a finite alphabet can be uniquely characterized by a \texttt{pAL} formula. As a consequence, any finite class of heap structures can be defined in \texttt{pAL}\(^5\). This extends our previous result in [2], that \texttt{pAL} has the power to distinguish between any two non-isomorphic heap configurations\(^6\). However, the far more interesting question, of whether and how could \texttt{pAL} be extended to describe recursive data structures and still preserve decidability, is subject to ongoing and future work.

For the rest of this section, let \( M = \{ X_1, \ldots, X_n \} \) be a given heap. We shall define a formula \( \phi_M \) such that \( [\phi_M]_M = 1 \) and, for any other heap \( M' \) such that \( [\phi_M]_{M'} = 1 \), we have \( M = M' \). For a finite word \( w \in \Sigma^{\ast} \), we denote by \( \text{Pref}(w) \) the set of all its prefixes, including \( w \). For a set \( X \in M \), a word \( w \in X \) is elementary if and only if it has at most two prefixes in \( X \) and at most one prefix in any other set \( Y \in M \), \( Y \neq X \). Formally, we have \( \text{Elem}_M(X) \triangleq \{ w \in X \mid |\text{Pref}(w) \cap X| \leq 2 \text{ and } \forall Y \neq X . |\text{Pref}(w) \cap Y| \leq 1 \} \).

An important property of the sets of elementary words is finiteness. This results as a consequence of the fact that both \( M \) and \( \Sigma \) are finite, since the length of any \( w \in \text{Elem}_M(X) \) is \( |w| \leq |M| + 1 \), thus \( |\text{Elem}_M(X)| \leq |\Sigma|\!(M+1) \). A dangling

\(^4\) Definition 2 in Section 4.

\(^5\) Even if a \texttt{pAL} formula, e.g. \( x \bowtie y \), is in general satisfied by an infinite number of heaps.

\(^6\) There we proved only that two structures are isomorphic if and only if they are models of the same \texttt{pAL} formulas.
word is a minimal undefined path in $\mathcal{M}$. Formally, we define $\text{Dang}_\mathcal{M}(X) = \{wa \mid w \in \text{Elem}_\mathcal{M}(X), a \in \Sigma, wa \not\in \bigcup \mathcal{M}\}$. Since $\text{Elem}_\mathcal{M}$ and $\Sigma$ are finite, so is $\text{Dang}_\mathcal{M}(X)$. With this notation, we define:

$$
\Gamma_\mathcal{M} \triangleq \bigcup_{X \in \mathcal{M}} \{w \otimes w' \mid w, w' \in \text{Elem}_\mathcal{M}(X)\} \cup
\bigcup_{X, Y \in \mathcal{M}, X \neq Y} \{\neg(w \otimes w') \mid w \in \text{Elem}_\mathcal{M}(X), w' \in \text{Elem}_\mathcal{M}(Y)\} \cup
\bigcup_{X \in \mathcal{M}} \{\neg(w \otimes w) \mid w \in \text{Dang}_\mathcal{M}(X)\} \cup \{\neg(a \otimes a) \mid a \in \Sigma \setminus \bigcup \mathcal{M}\} \quad (1)
$$

This set is constructed as follows: the first component (1) describes each object as a set of alias propositions composed of elementary sequences, the second component (2) distinguishes between objects using negated alias propositions and the third and fourth components (3) describe the dangling sequences. Notice that $\Gamma_\mathcal{M}$ is not minimal, since for instance in (2) it is sufficient to choose only one $w \in \text{Elem}_\mathcal{M}(X)$ and one $w' \in \text{Elem}_\mathcal{M}(Y)$. However, it is finite, according to our previous considerations. Intuitively, $\Gamma_\mathcal{M}$ contains all the necessary information to characterize $\mathcal{M}$, thus we shall take $\phi_\mathcal{M} \triangleq \bigwedge \Gamma_\mathcal{M}$. To show that $\mathcal{M}$ is a model of $\phi_\mathcal{M}$ is a trivial but tedious check. That it is indeed the only model, will be shown in the rest of this section.

**Lemma 4.** Let $\mathcal{M}$ be a heap with $X \in \mathcal{M}$, and $\Gamma_\mathcal{M}$ be the characteristic set defined in the previous. Then the following hold:

1. for each $w \in X$ there exists $w_0 \in \text{Elem}_\mathcal{M}(X)$ such that $\Gamma_\mathcal{M} \vdash w \otimes w_0$.
2. for all $w \not\in \bigcup \mathcal{M}$ we have $\Gamma_\mathcal{M} \vdash \neg(w \otimes w)$.
3. for any $x, y \in \Sigma^+$ we have $[x \otimes y]_\mathcal{M} = 1 \Rightarrow \Gamma_\mathcal{M} \vdash x \otimes y$ and $[x \otimes y]_\mathcal{M} = 0 \Rightarrow \Gamma_\mathcal{M} \vdash \neg(x \otimes y)$.

Notice that, from the third point of Lemma 4, and since $\Gamma_\mathcal{M}$ is satisfiable, hence consistent, we obtain that $\{\phi\}_\mathcal{M} = 1$ if and only if $\Gamma_\mathcal{M} \vdash \phi$. Thus, the set of formulas that are satisfied by $\mathcal{M}$ is finitely axiomatisable since $Th(\Gamma_\mathcal{M}) = \{\phi \mid \{\phi\}_\mathcal{M} = 1\}$, and $\Gamma_\mathcal{M}$ is finite by definition.

**Theorem 3.** Let $\mathcal{M}$ be a heap and $\phi_\mathcal{M}$ be the formula $\bigwedge \Gamma_\mathcal{M}$. If $[\phi_\mathcal{M}]_{\mathcal{M}'} = 1$, then $\mathcal{M} = \mathcal{M}'$.

**Example** Given $\Sigma = \{a, b, c\}$, the heap $\mathcal{M} = \{ab^c\}$ composed of one element pointed to by $a$ with a $b$ self loop is characterized by the formula $a \otimes ab \land \neg a \otimes c \land \neg a \otimes ac$.

4 Tableau Decision Procedure for pAL

A proof that uses natural deduction is mainly based on manually adding assumptions in order to reach contradictions (and deleting them afterwards).
makes, in general, natural deduction unsuitable for automated reasoning and motivates our preference for the method of analytic tableaux [24], an elegant and efficient proof procedure for propositional logic, which we subsequently extend to pAL. Traditionally, a tableau for a propositional formula ϕ is a tree having ϕ as the root node and subformulas of ϕ or negations of subformulas of ϕ as nodes. A tableau branch is said to be closed if it contains a formula together with its negation, and open otherwise. A tableau is said to be closed if and only if all its branches are closed. To check whether a formula ϕ is a tautology one builds the tableau for ¬ϕ, and infers that ϕ is a tautology if and only if the tableau eventually closes. In case at least one branch remains open, a counterexample for ϕ can be extracted.

$$
\frac{-\neg(x \land z) \ldots \neg t \land z}{-\neg x \land y} \quad (T_1) \quad \frac{x \land y}{x \land y} \quad (T_2) \quad \frac{x \land y}{y \land x} \quad (T_3) \quad \frac{-\neg x \land y}{-y \land x} \quad (T_4)
$$

$$
\frac{\varphi_1 \land \varphi_2}{\varphi_1, \varphi_2} \quad (T_5) \quad \frac{-\neg(\varphi_1 \land \varphi_2)}{-\varphi_1 \lor -\varphi_2} \quad (T_6) \quad \frac{-\neg \varphi}{\varphi} \quad (T_7) \quad \frac{\varphi \ldots -\neg \varphi}{\bot} \quad (T_8)
$$

**Fig. 5.** Tableau Expansion Rules

Figure 5 shows the tableau expansion rules for pAL. We consider that $x, y, z \in \Sigma^+$ and $t \in \Sigma^*$ that is, we can apply the rules also for an empty suffix ($t = \epsilon$). The tableau is constructed top-down. A rule whose hypothesis are of the form $\varphi \ldots \psi$ (namely $T_1$ and $T_8$) can be applied at a node, as soon as both $\varphi$ and $\psi$ are on the path from the root to the current node, order independent. Rule ($T_5$) expands by putting both $\varphi_1$ and $\varphi_2$ on the same branch of the tableau, while rule ($T_6$) creates two new branches, one containing $\varphi_1$ and the other one containing $\varphi_2$. All other rules expand by appending their conclusion to the current branch. We use rule ($T_8$) to close a branch, since $\bot$ does not expand any further. Each rule can only be applied provided that its conclusion does not already appear on the current branch, otherwise the procedure runs the risk of looping forever (for instance, applying one of rules $T_{3,4}$), without introducing any new formulas$^7$.

**Example** Figure 6 presents a sample run of the tableau procedure whose goal is to prove that, for some given $k \in \mathbb{N}$, $\phi_k \triangleq a \land ab \rightarrow a \land ab^k$ is a tautology. First, we eliminate the implication: $\phi_k = -a \land ab \lor -(a \land ab^k)$ and start the tableau procedure with $\neg \phi_k$ as the root node. To the right of each node occurs the number of the node(s) used in the hypothesis, followed by the name of the rule applied in order to obtain that node. In this example, the tableau closes after $k + 6$ steps. Branching lacks in this tableau because the rule ($T_6$) is never applied.

$^7$ The definition of a finer notion of redundancy is planned in the full version.
\[1\] \(\neg(a \otimes ab \wedge \neg(a \otimes ab^k))\)  \hspace{1cm} \[7\] \(\neg(ab^{k-1} \otimes a)\) \(5,6, T_1\)
\[2\] \(a \otimes ab \wedge \neg(a \otimes ab^k))\) \(1, T_7\)
\[3\] \(a \otimes ab\) \(2, T_5\)
\[4\] \(\neg(a \otimes ab^k))\) \(2, T_5\)
\[5\] \(ab \otimes a\) \(3, T_3\)
\[6\] \(\neg(ab^k \otimes a)\) \(4, T_4\)

\[k+5\] \(\neg(ab \otimes a)\) \(5, k + 4, T_1\)
\[k+6\] \(\bot\) \(5, k + 5, T_8\)

**Fig. 6. Tableau Example**

The tableau expansion rules can be easily understood with the natural deduction rules in mind. For instance, rule \((T_1)\) can be derived using (suffix), (\(\bot\)) and \((\neg I)\). Rules \((T_2)\) and \((T_3)\) are (suffix) and (suffix), respectively, while \((T_4)\) is easily derived using (sym) and \((\neg I)\). The rest of the rules correspond to the purely propositional part of the natural deduction system and are easy check. This (and the fact that the natural system is sound and complete) ensures that the tableau rules are sound i.e., if a tableau started with \(\neg \phi\) closes, then \(\phi\) is a tautology. The dual implication, if \(\phi\) is a tautology then every tableau started with \(\neg \phi\) will eventually close, will be dealt with in the following.

Note that the rules in Figure 5 do not cover the entire \texttt{pAL} syntax from Figure 3; the atomic propositions of the form \(x \leq y\) are not considered. The reason is that such propositions trivially evaluate to either true or false and could be eliminated from a formula a priori. For completeness, rules for the prefix test are given in [3].

The rest of this section is concerned with proving that the tableau method is both complete and effective. To handle the tableau rules in an uniform way, we use the unified notation of [24]: let an \(\alpha\)-rule be one of the rules \((T_1, \ldots, 5)\) and \(\beta\)-rule be the rule \((T_6)\). We denote the premises of a \(R\)-rule by \(R_1 \cdots R_m\) and its conclusions by \(\bar{R}_1 \cdots \bar{R}_m\), where \(R = \alpha, \beta\).

**Definition 2.** A set of formulas \(\Gamma\) is said to be downward closed if and only if it respects the following conditions:

- for no \(x, y \in \Sigma^+\), we have \(x \otimes y \neg(x \otimes y) \in \Gamma\),
- for any \(\alpha\)-rule, if \(a_1, \ldots, a_m \in \Gamma\), then \(\tilde{a}_1, \ldots, \tilde{a}_m \in \Gamma\),
- for any \(\beta\)-rule, if \(b_1, \ldots, b_n \in \Gamma\), then either \(b_1 \in S\) or ... or \(\bar{b}_m \in \Gamma\).

A tableau branch is said to be complete if no more rules can be applied to expand it. A tableau is said to be complete if and only if each of its branches is complete. It is manifest that an open complete tableau branch is a downward closed set. The following technical lemma is key to showing satisfiability of downward closed sets. We recall here the definition of the \(\not\preceq_{\Gamma}\) relation from Lemma 3. The following theorem is the main result of this section.

**Lemma 5.** For any downward closed set of formulas \(\Gamma\), \(\neg(x \otimes y) \in \Gamma\) implies \(x \not\preceq_{\Gamma} y\).
Theorem 4. Any downward closed set of formulas containing a finite number of alias propositions is satisfiable.

The proof of the above theorem uses the model construction technique from Lemma 3. The same method can be moreover used to derive a counterexample of a non-valid formula, starting from an open tableau branch. Before stating our completeness result for the tableau method, let us show that the method is effective. That is, each tableau procedure started with a finite formula as the root node, using the rules from Figure 5, eventually terminates.

Lemma 6. The tableau of a finite formula is finite.

Besides showing termination of the tableau procedure, the above lemma, together with Theorem 4 ensure that the tableau approach is complete.

Corollary 1. If a formula \( \varphi \) is a tautology then every complete tableau starting with \( \neg \varphi \) eventually closes.

In the light of the decidability result concerning pAL, we are next investigating the time complexity of the above satisfiability problem, and find that it is NP-complete. The proof uses Lemma 3 to show that satisfiability is in NP, and a reduction from the satisfiability problem for a set of boolean clauses with three literals (3-SAT) to show NP-hardness.

Theorem 5. The satisfiability problem for pAL is NP-complete.

5 An Effective Program Logic

In this section we demonstrate the possibility of using pAL as a weakest precondition calculus for imperative programs with destructive updating. Otherwise stated, we show that pAL is closed under applications of the weakest preconditions predicate transformers. Intuitively, this is a consequence of the fact that pAL formulas refer to finite portions of the heap, and also that straight-line statements affect bounded regions of the heap. Our proof of closure is constructive i.e., we define weakest preconditions in terms as predicate transformers directly on pAL. This is achieved by means of the sound and complete program logic defined on top of wAL [2]. Moreover, soundness and completeness of the pAL weakest precondition axioms are consequences of soundness and completeness in the case of wAL.

We consider a simple imperative language consisting of the following three atomics statements. Note that the statements of most object-oriented languages can be precompiled in this form, possibly by introducing fresh temporary variables:

\[ Stmt \ := \ uv = \text{null} \mid uw = \text{new} \mid uw = w \quad (\text{where } uv \not\subseteq w) \]

Here \( u, w \in \Sigma \) denote pointer variables, and \( u \in \Sigma^* \) is a (possibly empty) dereferencing path. The first statement resets the \( v \) field of the object pointed
to by \( u \), if \( u \neq e \), or the \( v \) top-level variable, otherwise. This may cause the builtin garbage collector recall all non-reachable objects. The second statement allocates a fresh object for further uses, and the third statement assigns its left-hand side the object pointed to by the right-hand side variable. The syntactic constraint that comes with the last statement is due to the following technical problem. The semantics of the assignment is given as the composition of two primitive operations: first one removes the \( v \) arc from the node pointed to by \( u \), and then it assigns it to \( w \). If \( uw \leq w \) and there are no other paths to the cell pointed to by \( w \), the garbage collection caused by the first operation removes the unreachable cell before the assignment is finished. The requirement \( uw \not\leq w \) is however sufficient to ensure that, in practice, this situation never occurs.

The axiomatic precondition semantics of this language has been introduced in [2], by defining a weakest precondition operator \( \overline{\text{pre}} \) on \( \text{wAL} \) formulas, and is briefly recalled here. For any transition relation over a sequence of statements \( \omega \in \text{Stmt}^+ \), \( \overline{\text{pre}} \) distributes over conjunction and universal quantification i.e., \( \overline{\text{pre}}(\omega, \varphi_1 \land \varphi_2) = \overline{\text{pre}}(\omega, \varphi_1) \land \overline{\text{pre}}(\omega, \varphi_2) \) and \( \overline{\text{pre}}(\omega, \forall X . \varphi) = \forall X . \overline{\text{pre}}(\omega, \varphi) \). For total transition relations we have \( \overline{\text{pre}}(\omega, \varphi) \Rightarrow \overline{\text{pre}}(\omega, \neg \varphi) \). If, moreover, the transition relation is total and deterministic, we have that \( \overline{\text{pre}} \) is its own dual i.e., \( \overline{\overline{\text{pre}}}(\omega, \varphi) \Leftrightarrow \overline{\text{pre}}(\omega, \neg \varphi) \). In the latter case, \( \overline{\text{pre}} \) distributes over disjunction and existential quantification too. These properties of \( \overline{\text{pre}} \) for total, deterministic programs allow us to define general inference rules for the precondition inductively on the structure of the postcondition. In particular, it is sufficient to define preconditions only for modalities, the rest of the atomic propositions in \( \text{wAL} \) being pure i.e., having model-independent denotations. Figure 7 (upper part) gives the precondition of primitive storeless operations \( \text{add}, \text{rem} \) and \( \text{new} \) for arbitrary modalities. This is generalized to the statements defined in the previous (lower part).

\[
\begin{align*}
\{ \exists X. X \backslash S \subseteq \Sigma \} & \quad \text{rem}(S,v) \{ (T \sigma) \\
\{ \exists X. \chi(S,T,X) = U \land \bigvee_{i=1,2} \psi_i(S,X,X) \} & \quad \text{add}(S,v,T) \{ (U \sigma) \\
& \quad \text{where} \quad \chi(S,T,X) \triangleq X \cup S((T^{-1}S)u)^*(T^{-1}X) \\
& \quad \psi_1(S,X,Y) \triangleq S((T^{-1}S)u)^*(T^{-1}X) \cap x = \emptyset \land (Y)u y \\
& \quad \psi_2(S,X,Y) \triangleq S((T^{-1}S)u)^*(T^{-1}X) \cap x \neq \emptyset \land (Y)\Sigma \\
\{ (T = S \cup \sigma \cap S \neq \emptyset) \lor (T \sigma) \} & \quad \text{new}(S,v) \{ (T \sigma) \\
\{ \exists S. \chi(S)u \land \overline{\text{pre}}(\text{rem}(S,v),\varphi) \} & \quad u = \text{null} \{ \varphi \} \\
\{ \exists S. \chi(S)u \land \overline{\text{pre}}(\text{rem}(S,v),\overline{\overline{\text{pre}}}(\text{new}(S,v),\varphi)) \} & \quad u = \text{new} \{ \varphi \} \\
\{ \exists S. \chi(S)u \land (T \sigma)u \land \overline{\text{pre}}(\text{rem}(S,v),\overline{\text{pre}}(\text{add}(S,v,T),\varphi)) \} & \quad u = w \{ \varphi \}
\end{align*}
\]

**Fig. 7.** \( \text{wAL} \) Weakest Preconditions
For the rest of this section, let $\sigma, \tau, \theta, u, v, w$ denote constant words, and $x, y, z$ denote variables ranging over words. We introduce the following notation: $\exists x \leq \sigma \cdot \varphi(x) \equiv \bigvee_{\tau \in \text{Pref}(\sigma)} \varphi(\tau)$. Since $\sigma$ is a finite word, so is the formula on the right. Figure 8 introduces a number of syntactic shorthands, providing context-dependent translations from wAL to pAL for them. That is, we do not translate the shorthands individually, but rather in an existentially closed context.

</tbody>
</table>

**Fig. 8.** wAL to pAL translation shorthands

We assert that all translations defined in Figure 8 preserve logical equivalence. To convince ourselves of this fact, let us perform the step-by-step derivation for the positive form of $\alpha_\sigma$. The rest of the formulas are translated along the same lines.

$\exists S . \langle S \rangle u \land \alpha_\sigma \equiv \exists S . \langle S \rangle u \land \sigma \in S \Sigma^* \iff \exists S . \exists x \leq \sigma . \langle S \rangle u \land \langle S \rangle x \land xv \leq \sigma \iff \exists x \leq \sigma . x \odot u \land xv \leq \sigma$

The goal of this section is to prove that the logic pAL is expressive enough to characterize the destructive updating program statements considered in the previous. The following theorem captures the result.

**Theorem 6.** For any sequence of statements $\omega \in \text{Stmt}^*$ and any formula $\varphi \in \text{pAL}[\Sigma]$, we have $\overline{\text{pre}}(\omega, \varphi) \in \text{pAL}[\Sigma]$.

The proof proceeds by deriving the weakest precondition for an arbitrary alias proposition $\sigma \odot \tau$ (equivalently written in wAL using the embedding rule) i.e., applying the rules in Figure 7. The result is then translated back from wAL to pAL using the shorthands from Figure 8. Then we can extend the result.
to arbitrary post-conditions using the distributivity properties for \( p \neq e \), and to arbitrary sequences of statements by induction on the length of the sequence.

It is important to notice that the translations from \texttt{pAL} to \texttt{wAL} and back are logical equivalences. Since the \( p \neq e \) operators defined on \texttt{wAL} formulas are sound and complete, according to the development in [2], we can infer the existence of a sound and complete weakest precondition calculus also for \texttt{pAL}.

6 Conclusions and Future Work

This paper concerns a deductive verification method for aliasing properties in imperative programming languages with destructive updating. Starting from previous work on storeless semantics and alias logic with a weakest precondition calculus \texttt{wAL}, we show that the satisfiability problem is undecidable but recursively enumerable. Next, we focus on a decidable subset \texttt{pAL} that allows to express sound and complete weakest preconditions. The kind of properties expressible in this logic are related to pointer aliasing, but also arbitrary finite heaps can be defined. We give two sound and complete proof systems for \texttt{pAL}, one based on natural deduction, and another based on analytic tableaux. The satisfiability problem for \texttt{pAL} is shown to be NP-complete. A tool based on the \texttt{pAL} framework is planned in the near future.

The main question related to the existence of a decidable program logic that can express non-trivial shape properties of heap is not fully answered. Although undecidable, the \texttt{wAL} logic offers a reach framework in which one can define decidable fragments having complete weakest precondition calculi. One such example is \texttt{pAL}. A still open question is the existence of a fragment of \texttt{wAL} that encompasses \texttt{pAL}, in which one can express properties such as reachability, circularity, etc. One such extension, called \texttt{kAL}, is currently under investigation. This logic is obtained from \texttt{pAL}, by considering words (over the heap alphabet) with integer counters (parameters indicating the repetition of a finite subword) and first order quantification over the counters. In this way we can express for instance the existence of an unbounded next-path between two pointers \( head \) and \( tail \); \( \exists k . \ head . (next)^k \land tail \), a property that is not expressible in \texttt{pAL}. We plan an extensive study of this logic, in order to cover both aspects of satisfiability and expressiveness.
